Abstract

A 27-year-old woman with headache and right peripheral facial nerve paresis persisting for over 25 days, and left hemiparesis for 2 days, which had all been gradually improving, was admitted to our hospital as she suddenly developed horizontal and vertical diplopia. She had right fourth and sixth cranial nerve pareses, papilledema, and right orbital venous congestion, and also experienced a seizure on the day of admission. Magnetic resonance (MR) imaging and MR venography revealed complete superior and inferior sagittal sinus thromboses and significant collateral venous channels, but no parenchymal lesion. Fourth and seventh cranial nerve pareses and the left hemiparesis resolved completely within 2 days, but she concurrently developed an episode of right hemiparesis, which lasted for 30 minutes. The patient recovered with medical therapy. MR venography showed recanalization of both sinuses. She was neurologically intact except for minimal right abducens nerve paresis at discharge, 40 days after admission. Multiple cranial nerve pareses with transient ischemic attack is an extremely rare manifestation of superior sagittal sinus thrombosis. Transient functional disturbance due to temporary reduction of tissue perfusion caused by overload of the collateral channels is more likely to be responsible for the transient ischemic attack and reversible ischemic neurological deficit.

Key words: cranial nerve paresis, reversible ischemic neurological deficit, sagittal sinus, sinus thrombosis, transient ischemic attack

Introduction

Dural sinus thrombosis is a rare but life-threatening pathology which requires special care for correct diagnosis and treatment. The clinical manifestations of superior sagittal sinus (SSS) thrombosis are nonspecific but characterized by the symptoms of either isolated intracerebral hemorrhage (ICH), i.e., headache, papilledema, blurred vision, or ICH symptoms together with seizures, focal deficits, progressive coma, and death. Sporadic cases of cranial nerve pareses associated with SSS thrombosis are rare and only three cases with transient ischemic attack (TIA) have been reported since 1966.

We describe a case of multiple cranial nerve pareses associated with TIA due to complete SSS and inferior sagittal sinus thromboses.

Case Report

A 27-year-old woman with complaints of headache and right facial nerve paresis persisting for over 25 days, and left hemiparesis for 2 days, which had all been gradually improving, was admitted to our hospital on May 30, 2000 as she suddenly developed horizontal and vertical diplopia. On the same day, she suffered vomiting and generalized convulsion. Neurological examination found she was somnolent and disoriented (Glasgow Coma Scale score 9) with neck stiffness, right fourth, sixth, and mild seventh cranial nerve pareses, papilledema, right orbital venous congestion, and mild left hemiparesis. Lumbar puncture revealed increased intracranial pressure (ICP) (31 cmH2O) and xanthochromia. Computed tomography (CT) had previ-
Fig. 1 Photographs showing peripheral facial (A) and abducens nerve pareses (B) on the right.

Fig. 2 Coronal T₁-weighted (A) and axial T₂-weighted (B) magnetic resonance images showing the signal changes consisted with indolent flow in the sagittal sinus.

Fig. 3 Right carotid angiogram, venous phase (A) and magnetic resonance venogram (B) showing no filling of the superior and inferior sagittal sinuses, and dilation of the vein of Labbé and other anastomotic veins together with a large number of collateral veins.

Fig. 4 Magnetic resonance venogram after treatment clearly showing both sagittal sinuses due to recanalization.

Previously been evaluated as normal, but magnetic resonance (MR) imaging on the day of admission revealed sagittal sinus thrombosis (Fig. 2). Carotid angiography and MR venography demonstrated complete SSS and inferior sagittal sinus thromboses and prominent collateral venous circulation (Fig. 3). Fourth and seventh cranial nerve pareses and the left hemiparesis resolved completely within 2 days. However, she suffered an episode of right hemiparesis, which lasted for 30 minutes, and depression of consciousness, so she was monitored in the intensive care unit until she recovered within 3 days. Detailed hematological and biochemical profiles, including serum protein C, protein S, and antithrombin III levels, were investigated. Coagulation profiles and collagen assays were measured. Focal or systemic sepsis was excluded. Medical therapy included heparin and warfarin administration with repeated prothrombin time controls, anticonvulsant and isotonic hydration therapies, and cerebrospinal fluid (CSF) drainage by lumbar puncture.

MR venography 18 days later displayed good recanalization of both sinuses (Fig. 4). Lumbar puncture findings and CSF pressure were within the physiological ranges. She was neurologically intact except for minimal right abducens nerve paresis at discharge 40 days later.

Discussion

SSS thromboses are identified at autopsy in 50% of cases, and the mortality is 56%. Thromboses of large dural sinuses may be spontaneous or follow direct infection, either systemic or of the adjacent epidural or subdural spaces. Aseptic (primary) intracranial venous occlusive disease tends to favor unpaired sinuses and is associated with pregnancy and puer-
perium, malignancy, hypercoagulable state (thrombophilia), lupus erythematosus, Behçet’s disease, familial Mediterranean fever, oral contraceptives, intracranial surgery, trauma, dehydration, cachexia, cardiac diseases, diabetes mellitus, and homocysteinuria. In our case, no etiological factor could be found. The ratio of women to men is 2:1. The mean age at the time of diagnosis was 27 years. Our female patient was also 27 years old.

Sinus thrombosis can only be identified by MR imaging, angiography, or MR venography. CT shows multiple irregular high dense foci mainly in the parietal lobes and the ventricular shift to one side, and the so-called “empty triangle” sign and gyral enhancement may be observed after administration of contrast medium. However, CT was not helpful in our case. MR imaging demonstrated the sinus thrombosis. Carotid angiography reveals delayed circulation, poor filling of the cortical veins, and absent or narrow SSS with a zigzag-shaped margin. In our case, the absence of both sagittal sinuses and presence of disseminated collateral venous circulation on angiography were confirmed by MR venography, which is the most reliable and noninvasive method for evaluating the venous sinuses.

Thromboses of the transverse and sigmoid sinuses are usually asymptomatic if the thrombosed sinus is nondominant or associated with rich collateral circulation. Furthermore, the clinical manifestation remains silent in chronic cases as good collateral venous circulation can develop. However, acute venous outflow obstruction leads to venous hypertension and resultant acute ICP increase. SSS thrombosis either occurs as isolated ICH, i.e., pseudotumor cerebri, which manifests as headache, papilledema, and/or blurred vision. The only presenting symptom in 53–66.7% of cases is persistent headache of variable duration, location, and severity. Papilledema occurs in 33% of cases, whereas visual loss in 25% of cases may progress to optic atrophy. CSF pressure usually increased to over 20 cmH2O. SSS thrombosis does not usually occur as isolated ICH, but manifests as seizures, focal deficits, progressive coma, and death (38%). Seizure is the second commonest sign (49%) after headache, which may progress to status epilepticus. In our patient, the headache suggestive of ICH preceded the focal neurological disturbance by 1–3 days. Hemiparesis, quadriplegia, or paraparesis is the third commonest symptom (19–48%).

SSS occlusion alone will not cause cranial nerve findings except for visual obscurcation and abducens nerve paresis due to increased ICP. Thus, the clinical findings may be due to increased ICP. Pseudotumor cerebri is known to be associated with ocular motility deficits, most commonly sixth cranial nerve paresis as a false-localizing sign. Very seldom fourth cranial nerve paresis and facial nerve involvement have been reported as false-localizing signs.

Fourth, sixth, and seventh cranial nerve pareses are individually reported to be false-localizing signs of intracranial hypertension. However, multiple cranial nerve pareses are hard to attribute only to intracranial hypertension. Venous thrombosis reduces the venous outflow from the brain and diminishes the effective blood flow to the involved area. Such venous engorgement causes white matter edema. The increased venous pressure may also cause hemorrhage. These processes may all contribute to ICP increase, but focal findings can be expected due to edema, hemorrhage, and/or venous infarction. In our patient, no edema, infarction, or hemorrhage could be identified, with the xanthochromic blood providing only evidence of minimal hemorrhage. The more likely mechanism of RIND and TIA in this patient is thought to be a transient functional disturbance due to a temporary reduction of tissue perfusion caused by the overload of the collateral channels.

A better outcome can be achieved with earlier diagnosis and treatment, particularly in patients with identifiable disorders causing SSS thrombosis, as well as thrombosis with relatively minimal extension. Systemic heparin administration remains the best treatment. Hydration with intravenous administration of isotonic fluids should be maintained to avoid an increase in ICH. If the presentation is delayed, treatment with acetazolamide and non-steroid anti-inflammatory drugs, and lumbar puncture (possibly shunt placement) can avoid the ophthalmologic complications of pseudotumor cerebri. Papilledema and visual disturbances should improve immediately after venous drainage is established from the retina and head of the optic nerve. If the diagnosis is established shortly after the thrombosis occurs, direct endovascular thrombolytic therapy with urokinase, streptokinase, or tissue plasminogen activator may be the best therapeutic option but should only be considered in a selective group of patients, probably those worsening under medical therapy. Long-term treatment after resolution of the acute phase consists of heparin and/or warfarin for over 3–6 months. In our case, no

Neurol Med Chir (Tokyo) 42, September, 2002
surgical intervention was needed since almost complete cure was achieved with medical therapy.
